

The Computation of Optical Flow

S. S. BEAUCHEMIN AND J. L. BARRON

University of Western Ontario

Two-dimensional image motion is the projection of the three-dimensional motion of objects, relative to a visual sensor, onto its image plane. Sequences of time-ordered images allow the estimation of projected two-dimensional image motion as either instantaneous image velocities or discrete image displacements. These are usually called the *optical flow field* or the *image velocity field*. Provided that optical flow is a reliable approximation to two-dimensional image motion, it may then be used to recover the three-dimensional motion of the visual sensor (to within a scale factor) and the three-dimensional surface structure (shape or relative depth) through assumptions concerning the structure of the optical flow field, the three-dimensional environment, and the motion of the sensor. Optical flow may also be used to perform motion detection, object segmentation, time-to-collision and focus of expansion calculations, motion compensated encoding, and stereo disparity measurement. We investigate the computation of optical flow in this survey: widely known methods for estimating optical flow are classified and examined by scrutinizing the hypotheses and assumptions they use. The survey concludes with a discussion of current research issues.

Categories and Subject Descriptors: I.2.10 [**Artificial Intelligence**]: Vision and Scene Understanding—*motion*; I.3.1 [**Computer Graphics**]: Hardware—*three-dimensional displays*; I.4.0 [**Image Processing**]: General—*image displays, image processing software*; I.4.8 [**Image Processing**]: Scene Analysis—*time-varying imagery*; I.4.10 [**Image Processing**]: Image Representation—*hierarchical*; I.5.0 [**Pattern Recognition**]: General

General Terms: Algorithms, Measurement, Theory

Additional Key Words and Phrases: Disparity image displacement, image motion, image velocity, multiple motions, parameter models, optical flow, transparency

1. INTRODUCTION

A fundamental problem in processing sequences of images is the computation of *optical flow*, an approximation to image motion defined as the projection of velocities of 3D surface points onto the imaging plane of a visual sensor. Optical flow is often a convenient and useful image motion representation. However, there exist other motion descriptors, some-

times more general than optical flow, such as parametric models of motion, or descriptors adapted to restricted contexts, such as when elements of the geometry of the scene or the motion of the visual sensor are partially or completely predetermined.

The importance of motion in visual processing cannot be understated: approximations to image motion may be

1.1 Motion and Structure Paradigms

Traditionally, approximations to image motion have been used to infer egomotion and scene structure. Towards this end, different motion and structure paradigms have been developed, sometimes using optical flow as an intermediate representation of motion, correspondences between image features, correlations, or properties of intensity structures. These paradigms are generally classified into three main groups:

Velocity. Three-dimensional motion and scene structure may be inferred from two-dimensional velocity fields [Hay 1966; Longuet-Higgins and Prazdny 1980; Prazdny 1979] by relating the motion and structure parameters to optical flow. These parameters include instantaneous translation and rotation rates and possibly surface parameters or relative depth. Figure 1 shows one frame and its corresponding optical flow field for the synthetic *Yosemite fly-through* sequence, produced by Lynn Quam at SRI.

Disparity. Image disparities, either established as image feature correspondences or local correlations, may be used to compute three-dimensional translation vectors, rotation matrices, and surface attributes [Longuet-Higgins 1981; Tsai et al. 1982].

Intensity. Image intensities and their derivatives are sometimes used directly to obtain motion and structure parameters,⁶ thus avoiding an explicit intermediate representation of image motion such as optical flow or disparity fields.

Usually, relating image motion estimates or intensity derivatives to three-dimensional motion and structure parameters results in sets of nonlinear equations. In addition, each of these paradigms has its merits and detractors, depending on the intended use and the characteristics of

the imagery. However, their evaluation is beyond the scope of this survey.

1.2 Optical Flow

The initial hypothesis in measuring image motion is that the intensity structures of local time-varying image regions are approximately constant under motion for at least a short duration [Horn and Schunck 1981]. Formally, if $I(\mathbf{x}, t)$ is the image intensity function, then

$$I(\mathbf{x}, t) \approx I(\mathbf{x} + \delta \mathbf{x}, t + \delta t), \quad (1.1)$$

where $\delta \mathbf{x}$ is the displacement of the local image region at (\mathbf{x}, t) after time δt . Expanding the left-hand side of this equation in a Taylor series yields

$$I(\mathbf{x}, t) = I(\mathbf{x}, t) + \nabla I \cdot \delta \mathbf{x} + \delta t I_t + O^2, \quad (1.2)$$

where $\nabla I = (I_x, I_y)$ and I_t are the first-order partial derivatives of $I(\mathbf{x}, t)$, and O^2 , the second and higher order terms, which are assumed negligible. Subtracting $I(\mathbf{x}, t)$ on both sides, ignoring O^2 and dividing by δt yields

$$\nabla I \cdot \mathbf{v} + I_t = 0, \quad (1.3)$$

where $\nabla I = (I_x, I_y)$ is the spatial intensity gradient and $\mathbf{v} = (u, v)$ is the image

velocity.⁷ Equation (1.3) is known as the *optical flow constraint equation*, and defines a single local constraint on image motion (see Figure 2). In the figure the normal velocity \mathbf{v}_\perp is defined as the vector perpendicular to the constraint line, that is, the velocity with the smallest magnitude on the optical flow constraint line. This constraint is not sufficient to compute both components of \mathbf{v} as the optical flow constraint equation is ill-posed.⁸ That is to say, only \mathbf{v}_\perp , the motion component in the direction of the local gradient of the image intensity function, may be estimated. This phenomenon is known as the *aperture problem* [Ullman 1979] and only at image locations where there is sufficient intensity structure (or Gaussian curvature) can the motion be fully estimated with the use of the optical flow constraint equation (see Figure 3). For example, the velocity of a surface that is homogeneous or containing texture with a single orientation cannot be recovered optically. Because the normal velocity is in the

⁷The row convention for vectors is used, thus $\mathbf{x} \cdot \mathbf{y} = \mathbf{x}\mathbf{y}^T$ represents inner product.

⁸The optical flow constraint equation is one linear equation in the two unknowns $\mathbf{v} = (u, v)$.

Figure 2. The optical flow constraint equation defines a line in velocity space.

Figure 3. Through apertures 1 and 3, only normal motions of the edges forming the square can be estimated, due to a lack of local structure. Inside aperture 2, at the corner point, the motion can be fully measured as there is sufficient local structure; both normal motions are visible.

direction of the spatial gradient ∇I , Equation (1.3) allows one to write

$$\mathbf{v}_\perp = \frac{-I_t \nabla I}{\|\nabla I\|_2^2}. \quad (1.4)$$

Thus, the measurement of spatiotemporal derivatives allows the recovery of normal image velocity.

From this definition, it becomes clear that for optical flow to be exactly image

motion, a number of conditions have to be satisfied. These are: a) *uniform illumination*; b) *Lambertian surface reflectance*, and c) *pure translation parallel to the image plane*. Realistically, these conditions are never entirely satisfied in scenery. Instead, it is assumed that these conditions hold locally in the scene and, therefore, locally on the image plane. The degree to which these conditions are satisfied partly determines the accuracy with which optical flow approximates image motion. Alternatively, one can measure the displacement of small image patches, for example by correlation, in short image sequences (usually two or three frames). Such *image displacements* constitute a valuable approximation to image velocity when certain conditions are met. In particular, the ratio of sensor translational speed to absolute environmental depth, the 3D vertical and horizontal sensor rotations, and the time interval between frames must be small quantities [Adiv 1985]. Optical flow may also be computed as the *disparity field* where, given two stereo images or two adjacent images in some sequence, features of interest in the images are extracted and matched via a correspondence process.

Essentially, performing 2D motion detection involves the processing of scenes where the sensor is moving within an environment containing both stationary

and nonstationary objects. Furthermore, visual events such as occlusion, transparent motions, and nonrigid objects increase the inherent complexity of the measurement of optical flow.

1.3 Hierarchical Processing

Traditionally, optical flow was computed using only one scale of resolution, usually defined by the visual sensor [Horn and Schunck 1981], leading to the problem of measuring large image motions. In this case, because of low sampling rates and aliasing effects, Equation (1.3) becomes inappropriate. A general way of circumventing this problem is to apply optical flow techniques in a hierarchical, coarse-to-fine framework. Hierarchical frameworks allow the images to be decomposed in different scales of resolution in the form of Gaussian or Laplacian pyramids.⁹ Because of a low-frequency representation at coarser resolutions, the optical flow constraint equation becomes applicable in the case of large image motions [Kearney et al. 1987]. In addition to handling fast motions, hierarchical processing also offers increased computational efficiency. In such frameworks, velocity or displacement estimates are cascaded through each resolution level as initial estimates subject to refinement. At the coarsest level, initial estimates are computed and then projected onto a finer level of resolution and refined once again. The final estimates are obtained when the refinement reaches the finest level of resolution (see Figure 4). Hierarchical processing is applicable to most optical flow techniques. For example, Glazer [1981] adapted Horn and Schunck's differential technique to such a framework, Anandan [1989] used a hierarchical area-based correlation method, Heeger [1988] proposed a hierarchical energy-based filtering technique in a Gaussian pyramid, and Bergen et al.

[1992] proposed hierarchical parametric models for optical flow.

1.4 Problems and Issues

Much progress has been made in optical flow computation and yet, its accurate estimation remains difficult because of numerous theoretical and practical reasons. Theoretically, we believe that optical flow, as an approximation to image motion, largely determines the lower bound on accuracy. In addition, scene properties such as surface reflectance and informative image events such as transparency and occlusion were, until recently, not adequately dealt with in most models of image motion.

Optical Flow and Image Motion. The interpretation of intensity variation as pure relative motion is restrictive because velocity is a geometric quantity independent of illumination conditions. Hence, estimating optical flow from intensity variation only approximates image motion. Conditions which make optical flow different from image motion include the absence of texture, in which case optical flow is zero, and when the true motion field violates the brightness consistency model used for its approximation [Horn 1987]. Uniform scene illumination and Lambertian surface reflectance are either explicitly or implicitly assumed in most current optical flow methods which use some form of the brightness consistency assumption. Highlights, shadows, variable illumination, and surface translucency are phenomena violating the assumption and have only been studied to a limited extent.¹⁰

Occluding Surfaces and Independently Moving Objects. The problem posed by occluding surfaces is currently being addressed by the research community. Occlusion is difficult to analyze, despite the fact that occlusion constitutes an important source of visual information: optical

⁹See Anandan [1989], Battiti et al. [1991], Enkelmann [1986], Glazer [1987].

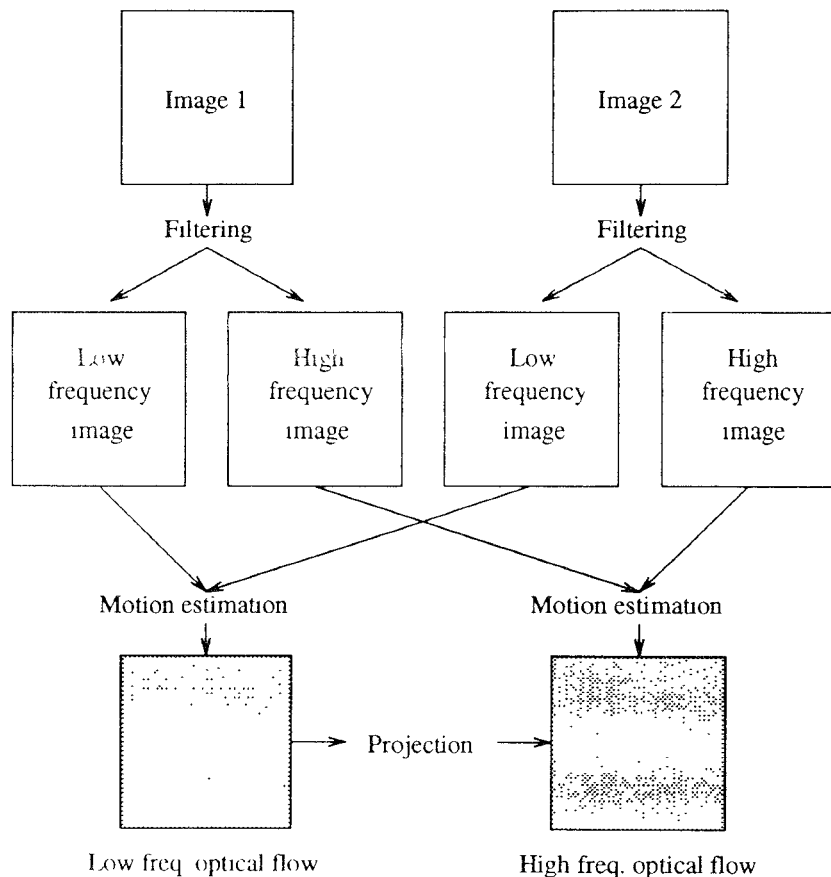

Figure 4. The hierarchical computational model.

flow at occlusion boundaries may be used to determine the direction of translation [Longuet-Higgins and Prazdny 1980] and segment the scene into independently moving surfaces [Adiv 1985; Thompson and Pong 1990; Yang and Adelson 1994]. Until recently, most optical flow techniques relied on a single-surface hypothesis [Horn and Schunck 1981], which is a rare visual event. The difficulty of handling occlusion lies in the fact that image surfaces may appear or disappear in time, misleading tracking processes and causing numerical artifacts in intensity derivatives.

Transparency. Transparent motions created by physically translucent sur-

faces are also found in imagery. The problem posed by transparent motions is mainly one of handling multiple motion distributions. Classical approaches to optical flow measurement which use single motion models are clearly inadequate [Barron et al. 1994]. Recently, mixed distributions and superposition principles have been applied to transparent motions [Bergen et al. 1992; Jepson and Black 1993; Shizawa and Mase 1991].

Practical issues in computing optical flow were addressed in a recent study [Barron et al. 1994] that analyzed nine techniques dating from 1981 to 1990, for ac-

curacy, density, and reliability of measurements.¹¹ To test the implementations of these algorithms, both synthetic and real data were used. The observed performance of these algorithms led to the following conclusions:

Prefiltering and Differentiation. Temporal smoothing is required in order to avoid aliasing, and numerical differentiation must be done carefully. The often-stated requirement that differential methods require image intensity be nearly linear with motions less than one spatial unit per frame arises from the use of only two frames, poor numerical differentiation, or input imagery corrupted by temporal aliasing. With two frames, derivatives are estimated using simple backward differences that are accurate only when the input is highly oversampled and the intensity structure is nearly linear. When temporal aliasing cannot be avoided, hierarchical methods, operating in a coarse-to-fine manner, provide better results.

Reliability Measures. The need for confidence measures to indicate the reliability of computed velocities cannot be understated. These confidence measures can be used to threshold optical flow fields or to weight velocities in post-measurement processing (in a motion and structure calculation, for example). Most current differential methods do not provide confidence measures. However, in Barron et al.'s study [1994], the smallest eigenvalue of a least-squares matrix [Simoncelli et al. 1991] was used successfully. Other possibilities, including the determinant of a Hessian matrix (Gaussian curvature) [Waxman et al. 1988], the condition number of a solution matrix [Fleet and Jepson 1990; Uras et al. 1988], the magnitude of local image gradients, the principal curvature values

[Anandan 1989], and the eigenvalues of a covariance matrix [Singh 1992] were examined [Barron et al. 1994].

Accuracy. Hierarchical correlation methods constitute robust motion measurement schemes for image sequences with significant contrast changes or large displacements and severe aliasing.¹² The test image sequences used by Barron et al. [1994] are all appropriately sampled with small motions (typically between one and four pixels per frame) and were favorable to differential approaches. In spite of this, and as opposed to differential-based test results, their experiments demonstrate that correlation methods experience difficulty with subpixel motions as their error depends on the closeness of image motion to an integer number of pixels. Hierarchical differential-based methods (using image warping or registration) may provide an alternative to correlation methods.

One of the purposes of Barron et al.'s study [1994] was to analyze the performance of different optical flow methods and to encourage others to compare numerical results with theirs. Towards this end, several authors now compare the performance of their techniques with those of this study for the same image sequences.¹³ In addition, some experimental work evaluating differential techniques has recently appeared [Handsack and Klette 1995]. Unfortunately, a quantitative analysis is often impossible for real image data (to obtain the correct optical flow, one needs the three-dimensional motion parameters as well as the three-dimensional depth values everywhere). In this case, only a qualitative analysis may be performed,

¹¹See Horn and Schunck [1981], Nagel [1983a, 1987], Uras et al. [1988], Lucas and Kanade [1981], Fleet and Jepson [1990], Fleet [1992], Heeger [1988], Anandan [1989], Singh [1990], and Waxman et al. [1988].

¹²Dutta et al.'s *stop-and-shoot* sequences constitute interesting image sequence examples [1989].

¹³See Bober and Kittler [1994], Haglund [1992], Weber and Malik [1993], Liu et al. [1993], Black and Jepson [1994], Xiong and Shafer [1994], Haddadi and Kuo [1992], and Fleet and Langley [1995b].

but it was observed that some optical flow fields, while being less accurate quantitatively, may appear better qualitatively, such as those obtained with methods incorporating global smoothing constraints. An obvious way to evaluate optical flow computations and yet avoid a quantitative analysis is to use the computed optical flow field in a motion and structure calculation and examine the accuracy of the 3D motion parameters. De Micheli et al. [1993] used optical flow fields obtained with the method of Uras et al. [1988] to estimate time-to-collision and angular velocity in a Kalman filter framework with good accuracy. More recently, Barron and Eagleson [1995] have proposed a motion and structure algorithm to compute general first- and second-order 3D motion and structure parameters from time-varying optical flow, also in a Kalman filter framework.

1.5 Scope and Purpose

There exist numerous computational models for estimating image velocity, which we classify into the following main groups: *intensity-based differential methods*,¹⁴ *frequency-based filtering methods*,¹⁵ and *correlation-based methods*.¹⁶ In addition, there exist methods for the computation of discontinuous or multiple-valued optical flow and techniques for performing temporal refinements of motion estimates as more information becomes available through the image-acquisition process. These meth-

ods are classified into the following groups: *multiple motion methods* and *temporal refinement methods*.

Most of these approaches can be understood as being comprised of three conceptual stages of processing: *prefiltering* (low-pass or band-pass) in order to extract signal structures of interest and to enhance the signal-to-noise ratio, *measurement extraction* of the basic image structures, such as spatiotemporal derivatives or local correlation surfaces, and *measurement integration* either by regularization, correlation, or a least squares computation. These approaches are thought to be broadly equivalent [Adelson and Bergen 1985, 1986] although differences in implementation can lead to significant differences in performance. Given this particular classification, this survey covers the optical flow techniques that do not require solving the correspondence problem. Hence, areas that are not covered by this survey are feature-based matching methods involving the correspondence problem and stereo approaches to image motion.

One of the most fundamental uses for optical flow is the computation of 3D motion and structure. Typically, these reconstruction algorithms are *ill-conditioned*¹⁷ and the accuracy of optical flow becomes of extreme importance. Achieving more accurate optical flow calculations requires not only careful attention to details, but also that realistic imaging properties be taken into account. In this survey, we examine both older and newer approaches to optical flow, with particular attention devoted to how the newer approaches address the accuracy, density, and reliability issues raised by Barron et al. [1994]. A recent survey [Aggarwal and Nandhakumar 1988] shows the current state-of-the-art up to 1988 not only for optical flow algorithms, but also for feature-based motion algorithms that require a solution to the correspondence problem, and for motion and

¹⁷As opposed to the computation of optical flow, which is *ill-posed*.

structure algorithms based on these two paradigms.

2. OPTICAL FLOW TECHNIQUES

We survey the following classes of optical flow techniques: a) *intensity-based differential methods*, b) *multiconstraint methods*, c) *frequency-based methods*, d) *correlation-based methods*, e) *multiple motion methods*, and f) *temporal refinement methods*. The boundaries between each class of methods are not always clear: Weng's method [1990] incorporates both phase-based and feature-based matching whereas Waxman et al.'s [1988] applies a differential scheme on time-varying edge maps. We classify the former as a phase-based method and the latter as a differential method. In addition, multiple motion and temporal refinement methods for optical flow overlap with other classes. However, their importance dictates that they be covered separately. Following this classification, we describe representative examples of current state-of-the-art work in optical flow measurement.

2.1 Differential Methods

Differential techniques compute image velocity from spatiotemporal derivatives of image intensities. The image domain is therefore assumed to be continuous (or differentiable) in space and time. Global and local first- and second-order methods based on Equation (1.3) can be used to compute optical flow. Global methods use (1.3) and an additional global constraint, usually a smoothness regularization term, to compute dense optical flows over large image regions.¹⁸ Local methods use normal velocity information in local neighborhoods to perform a least squares minimization to find the best fit for \mathbf{v} . The size of the neighborhood for obtaining a velocity estimate determines whether each individual technique is local or global. A surface or contour model

may also be used to integrate normal velocities into full velocity. Occlusion, manifested by discontinuous optical flow, can be analyzed by line processes, mixed velocity distribution, or parametric models. These techniques perform the segmentation of optical flow into regions corresponding to various independently moving objects or surfaces. Large 2D motions may be analyzed in a hierarchical framework, possibly in conjunction with warping methods.

2.1.1 Global Methods

Often, an explicit use of (1.3) is made in conjunction with a regularization term (usually a smoothness constraint).¹⁹ Combined, they form a functional which is minimized over the image domain. Regularization by requiring a slowly varying optical flow field was first introduced by Horn and Schunck [1981] to disambiguate normal measurements. It was justified by the claim that neighboring velocities, if corresponding to the same object surface, should be nearly identical. These constraints were used to define an error functional:

$$\int_D \left((\nabla I \cdot \mathbf{v} + I_t)^2 + \lambda^2 \text{tr}((\nabla \mathbf{v})^T (\nabla \mathbf{v})) \right) d\mathbf{x} \quad (2.1)$$

over a domain of interest D , where $\mathbf{v} = (u, v)$. The solution for \mathbf{v} is given as a set of Gauss-Seidel equations which are solved iteratively. Uniform illumination (at least locally) in the image domain of interest, orthographic projection, and pure translational motion parallel to the scene are conditions that must be met for the brightness constancy assumption ($dI/dt = 0$) to be satisfied. These hypotheses reduce the set of admissible visual events to restricted cases of realistic time-varying imagery and motivate the

¹⁸ Often, the entire image is considered.

¹⁹ See Aisbett [1989], Bergen et al. [1992], Enkelmann [1986], Glazer [1987b, 1987a], Horn and Schunck [1981], Nagel [1983a, 1983b, 1987], Schnorr [1991, 1992].

investigation of constraints generating more applicable equations. For instance, motion may cause a change in the density of features in a local image neighborhood. Schunck [1985] accounts for this by modifying (1.3), using the continuity equation from fluid dynamics and transport theory to obtain:

$$\nabla I \cdot \mathbf{v} + I(u_x + v_y) = -I_t. \quad (2.2)$$

This equation is equivalent to (1.3) but for an additional term containing flow divergence which expresses expansion or compression of an image neighborhood as it undergoes an *affine* transformation.²⁰ Nagel [1989] suggests that the optical flow constraint equation should be explicitly based on the geometric properties of the 3D scene and derives

$$\nabla I \cdot \mathbf{v} + I_t = 4I \left(\frac{\hat{\mathbf{z}} \dot{\mathbf{P}}^T}{\hat{\mathbf{z}} \dot{\mathbf{P}}^T} - \frac{\mathbf{P} \dot{\mathbf{P}}^T}{\mathbf{P} \dot{\mathbf{P}}^T} \right) \quad (2.3)$$

where \mathbf{P} is a 3D environmental point, $\dot{\mathbf{P}}$ is its 3D velocity, and $\hat{\mathbf{z}}$ is a unit vector along the line-of-sight axis. This equation assumes a known scene geometry. An experimental evaluation of these constraints [Equations (1.3), (2.2), and (2.3)] in Willick and Yang [1989] demonstrates that (1.3) has slightly better accuracy when applied to ray-traced synthetic data. Negahdaripour and Yu [1993] propose replacing (1.3) with a more general constraint that models a linear temporal transformation of the image intensity values. Prince and McVeigh [1992] derive the *variable brightness optical flow* equation for an application using MR (magnetic resonance) image sequences. This equation accounts for the fact that $dI/dt \neq 0$ in these images by modeling intensity changes over time as a function of MR parameters, motion, and an initial magnetically induced tag pattern. Luetgten et al. [1994] present a multi-

scale stochastic algorithm to regularize Horn and Schunck's smoothness constraint. The algorithm is noniterative and provides confidence measures (multiscale error covariance statistics) to determine the optimal resolution level of optical flow fields. The framework is generalizable to other regularization problems. Mukawa [1990] proposes a regularization method to compute optical flow with a global smoothness constraint and other constraints that model both diffuse and specular lighting effects (via Phong shading) for a moving object in a scene with one light source. The term being regularized is

$$\begin{aligned} E = & \sum_R (u_x^2 + u_y^2 + v_x^2 + v_y^2) \\ & + \lambda \sum_R (q + I_x u + I_y v + I_t)^2 \\ & + \mu \sum_R ((q_x - cI_x)^2 + (q_y - cI_y)^2) \\ & + \nu \sum_R (c_x^2 + c_y^2) = 0. \end{aligned} \quad (2.4)$$

The first term incorporates Horn and Schunck's smoothness constraint [1981]. The second term is the optical flow constraint equation with an additional term q that is the difference of diffuse and specular luminance over time, as first suggested by Cornelius and Kanade [1983]. The third and fourth terms exploit a relationship between the spatial derivatives of luminance (q_x and q_y) and the original image intensity derivatives: $q_x = cI_x$ and $q_y = cI_y$. c is a function that involves computing the ratios of diffuse luminance at different times. The fourth term ensures that c varies smoothly. λ , μ and ν are simply constants weighing the relative importance of each term in the minimization.

2.1.2 Local Models

Local models of velocity assuming single motion patterns are also common. For example, Lucas and Kanade use a local constant model for \mathbf{v} [1984, 1981] which is solved as a weighted least squares so-

²⁰An affine transformation includes translation, rotation, and foreshortening and may be expressed with six parameters: the image velocity and its first-order derivatives.

lution to (1.3). Velocity estimates are computed by minimizing

$$\sum_{\mathbf{x} \in R} W^2(\mathbf{x})(\nabla I(\mathbf{x}, t) \cdot \mathbf{v} + I_t(\mathbf{x}, t))^2, \quad (2.5)$$

where $W(\mathbf{x})$ denotes a window function and R is a spatial neighborhood. Solutions for \mathbf{v} are obtained in closed form. Modifications suggested by Simoncelli et al. [1991] allow the use of the eigenvalues of the least squares matrix involved in solving (2.5) as confidence measures in subsequent processing. Chu and Delp also use a local least squares approach [1989] and solve (1.3) with a total least squares calculation that accounts for errors in I_t and also for independent errors in I_x and I_y .²¹ Weber and Malik [1993] also use total least squares in their multiconstraint approach. Campani and Verri [1990] use a local model that assumes first-order variation in local motion measurements: an overconstrained system of equations is solved with least squares to recover velocity and its spatial derivatives. However, these local models tend to react poorly in the presence of multiple motions within the neighborhoods over which they operate.

The aperture problem may be analytically resolved by differentiating the optical flow constraint equations to obtain equations involving second-order intensity derivatives.²² These constraints generally provide two or more equations in the two components of \mathbf{v} and, when non-singular, can be used to obtain full motion estimates. For instance, Uras et al. [1988] use the constraint

$$(\nabla \nabla I) \mathbf{v}^T = -\nabla I_t \quad (2.6)$$

²¹Consider fitting a line $y = mx + b$ to noisy y values. In standard least squares, this is accomplished by minimizing the vertical distance of each y value from the fitted line assuming noiseless x values. In total least squares, it is assumed that there is noise in both the x and y values and the technique minimizes the perpendicular distance of y values from the fitted line [Zoltowski 1987].

²²See Haralick and Lee [1983], Nagel [1983a, 1987], Reichardt et al. [1988], Treliak and Pastor [1984], and Uras et al. [1988].

which results in an analytical expression for both components of \mathbf{v} at a single image point. Nagel [1987] shows that image points with high Gaussian curvature, such as grayvalue corners, allows the recovery of full velocity in closed form.²³ Both Haralick and Lee [1983] and Treliak and Pastor [1984] use a combination of (1.3) and (2.6) to overcome the aperture problem at individual image points and to estimate full velocity.

Another local approach, which avoids the need to estimate intensity derivatives altogether, uses the Gauss divergence theorem to convert the optical flow constraint equation into

$$\begin{aligned} & \int_V (I_x + I_y + I_t) dV \\ &= \int_S u I dy dt + \int_S v I dx dt \\ & \quad - \int_V I(u_x + v_y) dx dy dt \\ & \quad + \int_S I dx dy = 0, \end{aligned} \quad (2.7)$$

where S and V denote local integration over surfaces and volumes of intensity data [Gupta et al. 1993]. The size of the surface and volume neighborhoods must be sufficient to overcome the aperture problem.

2.1.3 Surface Models

Pioneering work by Longuet-Higgins and Prazdny [1980] examines the form of the optical flow field for a moving monocular observer in a rigid scene. They derive the well known *image velocity* equation, relating 3D motion and depth parameters to 2D image motion (approximated as optical flow). They show that these parameters could be recovered from optical flow and its first- and second-order derivatives. Longuet Higgins [1984] de-

²³Gaussian curvature may be expressed as $\det(\nabla \nabla I)$.

rives the conditions necessary to recover motion and structure from planar surface motion. It is shown that two planes with distinct surface orientations that are engaged in different 3D motions may have the same optical flow field. Waxman and Wohn [1985] describe the *dual* nature of these motion and structure parameters: one set of parameters can be derived from the other. Subbarao and Waxman [1985] demonstrate that these solutions are unique over time. Horn [1987] proves that multiple interpretations of a single optical flow field generated by arbitrarily shaped surfaces occur only rarely.

A number of planar motion techniques rely on normal velocity being available.²⁴ Waxman and Wohn's Velocity Functional method [1985] assumes that a velocity at a point on a curved surface can be approximated by a second-order Taylor series expansion about that point. For velocity $\mathbf{v} = (u, v)$, one obtains

$$\begin{aligned} \mathbf{v}(x, y) = \mathbf{v}(0, 0) + \frac{\partial \mathbf{v}}{\partial x} + \frac{\partial \mathbf{v}}{\partial y} + \frac{1}{2} \frac{\partial^2 \mathbf{v}}{\partial x^2} \\ + \frac{\partial^2 \mathbf{v}}{\partial x \partial y} + \frac{1}{2} \frac{\partial^2 \mathbf{v}}{\partial y^2}. \end{aligned} \quad (2.8)$$

Using the normal velocity constraint equation, $v_n = \mathbf{v} \cdot \mathbf{n}$, a linear equation in twelve unknowns, the two components of \mathbf{v} and their first- and second-order derivatives, are obtained. Given twelve or more normal velocities in a local neighborhood on the curved surface, these parameters can be recovered. In the event that the local surface is planar, then

$$\frac{\partial^2 \mathbf{v}}{\partial x^2} = \left(2 \frac{\partial^2 v}{\partial x \partial y}, 0 \right),$$

²⁴The measurement of first-order spatiotemporal density derivatives allows the computation of normal velocity.

$$\frac{\partial^2 \mathbf{v}}{\partial y^2} = \left(0, 2 \frac{\partial^2 u}{\partial x \partial y} \right), \quad (2.9)$$

allowing (2.8) to be written as one equation in eight unknowns. Hence, only eight normal velocities are required to recover the velocity of a planar surface.

Murray and Buxton [1984] derive a relation between normal velocity parameters of a planar surface, leading to a linear equation of the form

$$\|\mathbf{v}_\perp\|_2^2 = \mathbf{c} \cdot \mathbf{p}, \quad (2.10)$$

where vectors \mathbf{c} and \mathbf{p} contain expressions for image coordinates of normal velocity, the 3D motion parameters and the planar surface normal. Given eight normal velocities, the components of \mathbf{p} can be determined and full velocity is obtained as:

$$\begin{aligned} \mathbf{v} = \left(p_1 x + p_2 y - p_3 f + p_7 \frac{x^2}{f} + p_8 \frac{xy}{f}, \right. \\ \left. p_4 x + p_5 y - p_6 f + p_7 \frac{xy}{f} + p_8 \frac{y^2}{f} \right). \end{aligned} \quad (2.11)$$

Further mathematical manipulation of \mathbf{p} yields equations for the recovery of 3D motion parameters and surface orientation. If the aperture problem cannot be overcome for some image locations in a neighborhood, but surface parameters can be estimated, then, because of the use of a surface model, an image velocity for each of these locations may be inferred.

2.1.4 Contour Models

Many differential approaches to image motion estimation rely on the presence of contours or edges in image sequences.²⁵ The computational stages of these methods consist of the extraction of relevant image contours with prefiltering tech-

²⁵See Buxton and Buxton [1984], Duncan and Chou [1992], Hildreth [1984], Perrone [1990], and Waxman et al. [1988]

Figure 5. If at least two normal flow estimates along a contour are different, then the full velocity of the contour can be uniquely determined.

niques followed by a differential estimation of image motion. Essentially, contours or edges exhibit strong signal-to-noise ratios which facilitate their extraction. In addition, it is a common belief that they correspond to significant image structures, although this claim cannot be supported in any rigorous sense [Fleet 1992]. In addition, computing optical flow at edges often leads to sparse flow fields (usually, 10% of the field or less, depending on the density of edges).

Hildreth [1984] proposes a smoothness constraint to be applied to normal velocity estimates along contours extracted from time-varying images. For a contour S , the normal velocity estimates should minimize

$$\int \frac{\partial \mathbf{v}}{\partial S} dS. \quad (2.12)$$

If at least two normal velocity estimates along S are different, then the minimization of the preceding integral yields a

unique velocity field at contour S (see Figure 5). In practice, the functional

$$\int \left(\frac{\partial \mathbf{v}}{\partial S} \right)^2 + \beta (\mathbf{v} \cdot \hat{\mathbf{n}} - \|\mathbf{v}_\perp\|_2)^2 dS, \quad (2.13)$$

where $\hat{\mathbf{n}}$ is a unit vector in the direction of \mathbf{v}_\perp , is minimized along contours. β is a weighting factor and $(\mathbf{v} \cdot \hat{\mathbf{n}} - \|\mathbf{v}_\perp\|_2)^2$ expresses the squared difference between estimated normal velocity and that predicted by the solution. Gong and Brady formulate a similar constraint to be minimized which includes a least squares difference term for tangential velocity [1990]:

$$\int \left(\frac{\partial \mathbf{v}}{\partial S} \right)^2 + \beta (\mathbf{v} \cdot \hat{\mathbf{n}} - \|\mathbf{v}_\perp\|_2)^2 dS + \alpha (\mathbf{v} \cdot \hat{\mathbf{t}} - \|\mathbf{v}_\parallel\|_2)^2 dS, \quad (2.14)$$

where $\hat{\mathbf{t}}$ is a unit vector perpendicular to $\hat{\mathbf{n}}$ and α is a scalar expressing the confi-

dence associated with the tangential component of \mathbf{v} , proportional to the determinant of the Hessian matrix of the underlying intensity structure. They demonstrate that the tangential component of \mathbf{v} can be reliably estimated wherever the determinant of the Hessian is nonzero.

Buxton and Buxton's method [1984] for estimating optical flow is based on a model of the motion of edges in image sequences. They note that the signal-to-noise ratio is enhanced at locations of significant image features such as edges. Their approach, guided by psychophysical evidence of spatiotemporal filtering in human early visual processes, is a direct extension of the Marr and Hildreth center-surround edge detection operator [1980]. They compute spatiotemporal zero-crossings by convolving

$$S(\mathbf{x}, t) = - \left(\left(\nabla^2 + \frac{1}{u^2} \frac{\partial^2}{\partial t^2} \right) G(\mathbf{x}, t) \right) \quad (2.15)$$

with an image sequence, where the first term is the d'Alembert operator and the second term is a Gaussian function, given by

$$G(\mathbf{x}, t) = u \left(\frac{\alpha}{\pi} \right)^{3/2} e^{-\alpha (\|\mathbf{x}\|_2^2 + u^2 t^2)}, \quad (2.16)$$

where the parameters α and u control the spread of the envelope. Normal velocities can then be estimated at zero-crossings by computing the partial first-order derivatives of $S(\mathbf{x}, t)$ as

$$\mathbf{v}_\perp = \frac{S_t \nabla S}{\|\nabla S\|_2^2} \quad (2.17)$$

with a least squares calculation. The choice for the values of the parameters α and u is made a priori as the distribution of edges in the image is unknown.

Duncan and Chou define a temporal edge detector that minimizes the effects of temporal variations in illumination [1992]. The edge detector is the second-order temporal derivative of a Gaussian

function:

$$\begin{aligned} S_t(\mathbf{x}, t) &= \frac{\partial^2 G(t)}{\partial t^2} \\ &= \frac{-2s^3}{\sqrt{\pi}} (1 - 2s^2 t^2) e^{-s^2 t^2} \end{aligned} \quad (2.18)$$

which is convolved in time with the image sequence to produce a set of zero-crossings induced by moving edges. The authors theoretically and experimentally show that variance in illumination does not create zero-crossings in $S_t(\mathbf{x}, t)$. Central differences are used to estimate the first-order derivatives of S_t in local neighborhoods. Normal velocities are computed as

$$\nabla S_t \cdot \mathbf{v}_\perp - \frac{\partial S_t}{\partial t} = 0, \quad (2.19)$$

which is equivalent to the usual optical flow constraint equation. Lines defined by \mathbf{v}_\perp are then intersected in local image regions to obtain full velocity estimates. Successful experiments are presented with synthetic images containing significant illumination variations.

Waxman et al. [1988] apply spatiotemporal filters to edge maps in order to measure velocity at edges extracted with DOG zero-crossings [Marr and Hildreth 1980]. Given a binary edge map $E(\mathbf{x}, t)$, an *activation profile* $A(\mathbf{x}, t)$ is created by smoothing the edge map with a spatiotemporal Gaussian filter:

$$A(\mathbf{x}, t) = G(\mathbf{x}, t, \sigma_x, \sigma_y, \sigma_t) * E(\mathbf{x}, t) \quad (2.20)$$

to which a differential method is applied. At edge locations, where the Gaussian profiles are centered, the spatial gradient of A should be zero, and therefore a second-order approach is adopted. The velocity estimates are given by

$$\mathbf{v} = \begin{pmatrix} \frac{A_{xt} A_{yy} - A_{yt} A_{xy}}{A_{xx} A_{yy} - A_{xy}^2}, \\ \frac{A_{yt} A_{xx} - A_{xt} A_{xy}}{A_{xx} A_{yy} - A_{xy}^2} \end{pmatrix}, \quad (2.21)$$

where derivatives of A are computed by convolving the appropriate Gaussian derivative kernels with the edge maps.

A different method for tracking edges via zero-crossings is to use a radial configuration of DOG operators. Perrone [1990] presents such a model to measure normal velocities of moving edges. In the radial configuration, temporal differences in the responses of the operators provide sufficient information towards determining normal velocity. A constant model can then be applied to the normal velocity distributions to obtain full velocity.

2.1.5 Multiconstraint Methods

Multiconstraint methods use multiple instances of Equation (1.3) or (2.6) to provide unambiguous expressions for image motion at single image points.²⁶ Liu et al. [1993] use Equations (1.3) and (2.6): they expand the spatiotemporal image with Hermite polynomials and solve for \mathbf{v} using standard least squares. Residual of fit, condition number, and determinant of the least squares matrix act as confidence measures on the final optical flow field. Overconstrained systems of equations can also be obtained with multiple light sources [Woodham 1990] or by using images acquired with visual sensors tuned to different regions of the light spectrum. Spectral images include those in the visible (three color planes) and infrared spectrum. Markandey and Flinchbaugh [1990] show that their multispectral approach produced similar accuracy to Horn and Schunck's algorithm [1981] for synthetic image data and an outdoor scene.

Functions other than (or coupled with) intensity may be substituted in the optical flow constraint equation to obtain overconstrained systems. These functions can be thought of as the output of opera-

tions applied to the image intensities. For example, responses of pairs of linearly independent filters can be used jointly with the optical flow constraint equation for this purpose [Srinivasan 1990; Sobey and Srinivasan 1991; Weber and Malik 1993]. Mitiche et al. [1987] use an overconstrained system of equations constructed from the optical flow constraint equation for the same point in a number of different images, derived from the original one, generated by applying functions to compute local values for contrast, average, variance, entropy, median, and power content. Srinivasan [1990] proposes a similar approach, using an overconstrained system of equations derived from images that are generated by applying six specialized spatiotemporal filters on the original images. However, the aperture problem still cannot be resolved when facing singularities in overconstrained systems of equations: these occur for particular intensity structures, including uniform intensity regions, highly structured or periodic textures, etc.

2.1.6 Hierarchical Approaches

Differential optical flow methods also exhibit problems with large 2D motions, due to low sampling rates, thus violating the Shannon sampling theorem. Applying differential methods in a coarse-to-fine manner alleviates such problems. Image warping may be used to keep the images sufficiently well registered at the scale of interest so that numerical differentiation can be performed. Bergen et al.'s hierarchical framework [1992] unifies several different model-based optical flow methods. Using a parametric model based on affine transformations, scene rigidity, surface planarity, or general motion in an image region allows one to both judge the quality of the fit to the data (perhaps splitting the region if necessary), and to fill in sparse optical flow fields with the computed parameters.

Differential-based hierarchical frameworks are proposed by Glazer [1987a, 1987b], Enkelmann [1986], and Battiti et

²⁶See Woodham [1990], Liu et al. [1993], Srinivasan [1990], Sobey and Srinivasan [1991], Weber and Malik [1993], Mitiche et al. [1987], and Tistarelli and Sandini [1990].

al. [1991]. In addition, Bergen et al. [1992] show that many models of motion can be expressed within a hierarchical framework. Adaptive hierarchical methods with respect to scale have also appeared in Battiti et al. [1991], Koch et al. [1991], Whitten [1990], and Luetthgen et al. [1994].

2.2 Frequency-Based Methods

A second class of optical flow techniques is based on the use of velocity-tuned filters. These techniques use orientation sensitive filters in the Fourier domain of time-varying images.²⁷ Among advantages brought by these methods, it is found that motion-sensitive mechanisms operating on spatiotemporally oriented energy in Fourier space can estimate motion in image signals for which matching approaches would fail. For example, the motion of random dot patterns may be difficult to capture with feature-based or correlation-based methods, whereas, in Fourier space, the resulting oriented energy may be more readily extracted to compute motion [Adelson and Bergen 1985].

The Fourier transform of a translating 2D intensity signal specified in (1.1) is

$$\hat{I}(\mathbf{k}, \omega) = \hat{I}_0(\mathbf{k}) \delta(\mathbf{v}^T \mathbf{k} + \omega), \quad (2.22)$$

where $\hat{I}_0(\mathbf{k})$ is the Fourier transform of $I(\mathbf{x}, 0)$ and \mathbf{x} denotes spatial position. δ is a Dirac delta function and \mathbf{k}, ω denote spatiotemporal frequency. This yields the optical flow constraint equation in frequency space:

$$\mathbf{v}^T \mathbf{k} + \omega = 0, \quad (2.23)$$

which shows that the velocity of a translating 2D pattern is a function of its spatiotemporal frequency and forms a

plane through the origin of the Fourier space.

2.2.1 Orientation Selective Filtering

Adelson and Bergen [1985] propose a class of computational schemes that exploits the fact that detecting image motion is equivalent to extracting spatiotemporal orientation. Gabor filtering is presented as a technique for extracting spatiotemporal energy. A Gabor filter is a Gaussian function multiplied by a sine or cosine wave. For example, the function

$$\begin{aligned} G(\mathbf{x}, t) = & \frac{1}{(2\pi)^{3/2} \sigma_x \sigma_y \sigma_t} \\ & \times e^{-(x^2/2\sigma_x^2 + y^2/2\sigma_y^2 + t^2/2\sigma_t^2)} \\ & \times \sin(2\pi(\mathbf{x} \cdot \mathbf{k} + \omega t)) \end{aligned} \quad (2.24)$$

is a 3D sine (odd) Gabor filter, where (\mathbf{k}, ω) is the central frequency at which response amplitude peaks. Adelson and Bergen note that the response pattern of such filters is affected by the contrast of the signal: stimuli with low contrast generate low response amplitudes and vice versa. Because the measurement of velocity is independent of contrast amplitudes, it is suggested that one use ratios of responses from different filters for the extraction of velocity estimates.

Jähne [1990] demonstrates that detection of spatiotemporal orientation is analogous to eigenvalue analysis of the inertia tensor. For instance, a point at the origin of Fourier space corresponds to a region of constant intensity and corresponds to zero eigenvalues in tensor space. Also, a line in frequency space is a spatially oriented pattern moving with constant velocity, and its normal velocity can be obtained with the eigenvector corresponding to the zero eigenvalue. Finally, a plane through the origin expresses a spatially distributed pattern moving with constant velocity and the eigenvector associated with the maximum eigenvalue of the inertia tensor gives the full velocity of the pattern. Hence, Jähne [1990] suggests the use of

²⁷ See Adelson and Bergen [1985], Fleet and Jepson [1990], Grzywacz and Yuille [1990], Heeger [1988], and Watson and Ahumada [1985].

inertia tensor analysis for detecting spatiotemporal orientation and to avoid the computational expense arising from the large number of filters involved in both Heeger's [1988] and Fleet and Jepson's methods [1990]. However, this algorithm was only tested on simulated image data. Barman et al.'s work [1991] is similar to Jähne's, as they use spatiotemporal filtering to recover both velocity (and depth-scaled disparity in the case of motion stereo) and acceleration. A tensor is computed from the response of six or more quadrature filters, evenly spread in one half of the Fourier space. Eigenvalues and eigenvectors of the tensor allow one to determine which of several formulae can be used to compute full or normal velocity, if possible. Acceleration may also be recovered as curvature of the spatiotemporal surface in frequency space [Barman 1991].

Often, these frequency-based velocity techniques are presented as biological models of human motion sensing: Watson and Ahumada [1985] define an orientation-selective mechanism that agrees with psychophysical measurements of human motion sensing. Their mechanism uses a combination of 2D spatial Gabor functions and 1D temporal filters tuned to several orientations for the estimation of local image velocity. The integration of the responses of these sensors discriminates local measurements as each sensor within a directional group provides a linearly independent component of the velocity vector. Grzywacz and Yuille [1990] also propose a frequency-based model of visual motion sensing. Their model uses 3D orientation-selective Gabor filters to measure motion energy in frequency space. Estimates of velocity are also obtained by integrating the responses of populations of filters on a local basis.

2.2.2 Phase-Based Filtering

The method developed by Fleet and Jepson [1990] defines component velocity in terms of the instantaneous motion of level phase contours in the output of

band-pass velocity-tuned Gabor filters.²⁸ These filters are used to decompose the input signal according to scale, speed, and orientation. Each filter output is complex-valued and can be expressed as

$$R(\mathbf{x}, t) = \rho(\mathbf{x}, t)e^{i\phi(\mathbf{x}, t)}, \quad (2.25)$$

where $\rho(\mathbf{x}, t)$ and $\phi(\mathbf{x}, t)$ are the amplitude and phase part of the output signal. The component 2D velocity in the direction normal to level phase contours is given by

$$\mathbf{v}_\perp = \frac{-\phi_t(\mathbf{x}, t)\nabla\phi(\mathbf{x}, t)}{\|\nabla\phi(\mathbf{x}, t)\|_2^2}. \quad (2.26)$$

$\phi_t(\mathbf{x}, t)$ is the temporal derivative of the phase and $\nabla\phi(\mathbf{x}, t)$ is its spatial gradient. Phase derivatives are computed using the identity

$$\nabla\phi(\mathbf{x}, t) = \frac{\text{Im}[R^*(\mathbf{x}, t)\nabla R(\mathbf{x}, t)]}{|R(\mathbf{x}, t)|^2}, \quad (2.27)$$

where R^* is the complex conjugate of $R(\mathbf{x}, t)$, $\nabla R(\mathbf{x}, t)$ is the gradient of $R(\mathbf{x}, t)$, and Im denotes the imaginary part of a complex number. Fleet and Jepson relate velocity to local phase information because of the relative insensitivity of the phase signal to amplitude variations due to changes in scene illumination. These distortions are often a consequence of the geometry of perspective projection. Component velocity can be obtained from the output of each velocity-tuned channel on the condition that the phase signal is stable. Usually, instabilities are associated with neighborhoods about phase singularities that may be detected with a constraint stating that the distance between the instantaneous frequency and the peak tuning frequency of the filter should be minimal. Such a constraint, when met, is sufficient to avoid velocity estimation at phase singularities.

²⁸The term *component* velocity is used to denote the velocity normal to local phase structure whereas *normal* velocity denotes velocity normal to local intensity structure.

Because each channel is considered independently, there may be multiple measurements at a single image location. Then, if there is a sufficient number of estimates, full velocity is recovered at a single point or in a small neighborhood by solving a linear system of equations relating the measurements to an affine model of optical flow. As currently formulated, Fleet and Jepson's method does not provide confidence measures. There is also a requirement for a large number of filters to cover frequency space. In addition, it is interesting to note that local phase information is also used in stereopsis for the measurement of image disparities by Jenkin et al. [1991] and Langley et al. [1991]. Weng [1990] demonstrates that the phase part of a signal in a particular frequency channel provides sufficient information to reconstruct the signal within a multiplicative constant. Windowed Fourier phase is used as the correlation primitive in Weng's matching algorithm.

Phase is more robust than either intensity derivatives or energy-based filter responses for varying scene illumination. This can be seen intuitively by considering a signal of the form $A \cos(\omega t + \phi)$. Changing the amplitude, A , of the signal will change its derivative values or the response of an energy based (amplitude-squared) filter, but will have little effect on the phase of the signal or its derivatives. Phase-based methods will also respond to the component velocities of multiple motions due to occlusion or transparency, although a suitable measurement integration method, such as a mixed velocity model, is required to cluster them into the correct full velocities. Typically, frequency-based methods do not provide a means of assigning confidence to the computed velocities. Thresholds may be provided [Fleet and Jepson 1990; Heeger 1988] but their use is binary: either a velocity is found at an image location or one is not.

2.2.3 Hierarchical Approaches

Heeger [1980] presents a computational model for the estimation of image veloc-

ity which uses quadrature pairs of spatiotemporal Gabor filters. A family of Gabor-energy filters, tuned to the same spatial frequency band but to different spatial orientations, is defined. The magnitude of the spatial frequency tuning is, therefore, invariant and other sets of filters can be designed for different frequency channels. However, a single set of such filters can be cascaded through a Gaussian pyramid in order to cover different channels. For a translating 2D pattern, the responses of these filters are concentrated about a plane in frequency space. Parseval's theorem is used to derive the expected responses $R_i(\mathbf{v})$ of the Gabor-energy filters for a translating stimulus:

$$R_i(\mathbf{v}) = e^{-4\pi^2 \sigma_x^2 \sigma_y^2 \sigma_t^2 H_i(\mathbf{v}, \mathbf{k}_i, \omega_i)} \quad (2.28)$$

where

$$H_i(\mathbf{v}, \mathbf{k}_i, \omega_i) = \frac{\mathbf{v} \cdot \mathbf{k}_i + \omega_i}{(u\sigma_x\sigma_t)^2 + (v\sigma_y\sigma_t)^2 + (\sigma_x\sigma_y)^2}.$$

The variables σ_x , σ_y , and σ_t are the standard deviations of the Gabor filters. If m_i is the measured energy for filter i , and \bar{m}_i and \bar{R}_i are the sums of m_i and R_i which belong to the set of filters M_i having the same spatial orientation as the i th filter:

$$\bar{m}_i = \sum_{j \in M_i} m_j$$

$$\bar{R}_i = \sum_{j \in M_i} R_j(\mathbf{v}),$$

then a nonlinear least squares solution for \mathbf{v} which minimizes the difference between the predicted and measured energies,

$$f(\mathbf{v}) = \sum_{i=1}^n \left(m_i - \bar{m}_i \frac{R_i(\mathbf{v})}{\bar{R}_i(\mathbf{v})} \right)^2, \quad (2.29)$$

should yield the correct estimate for \mathbf{v} . Certainty measures for velocity estimates are expressed as conditional probability densities. A computationally efficient method of convolving Gabor fil-

ters, exploiting their separability properties, is also presented by Heeger.

2.3 Correlation-Based Methods

Numerical differentiation is sometimes impractical because of small temporal support (only a few frames) or poor signal-to-noise ratio [Barron 1994]. In these cases, differential or frequency approaches may not be appropriate and it is natural to consider matching methods.

2.3.1 Correlation-Based Matching

Typically, good, matchable features, such as corner points, are sparse whereas poor, easily mismatched features, such as edges, are denser. Even when reasonably unique features are available, establishing the correct correspondences can be problematic. Also further complicating matters is occlusion of features that may lead to matching errors.

Correlation-based matching approaches are less sensitive to these problems: they do not rely on the presence of significant image features and variable correlation window sizes can be used near occlusion boundaries to handle multiple motions [Little 1992]. These approaches define displacement (which is an approximation to velocity) as a shift that yields the best fit between contiguous time-varying image regions. Most of these approaches originate from computational stereopsis, where the task is to correlate image regions of a pair of images taken from different viewing positions, under perspective projection. It is assumed that, at least locally, distortions caused by the shift in the viewing angle are negligible [Jenkin et al. 1991]. Matching image regions often amounts to maximizing a similarity measure. In particular, a correlation coefficient between two functions f and g is defined as the integral of their product:

$$\int_D f(x + \delta x) g(x) dx.$$

Finding δx which maximizes this integral amounts to finding the shift between f and g , if $f(x + \delta x) = g(x)$.

Kories and Zimmerman use a monotonicity operator for matching image regions in adjacent images [1986]. The operator is a 3×3 window in which the central grayvalue is compared with its neighbors and classified according to the number of grayvalues that have a lower value than the central one. The matching process proceeds by first merging adjacent grayvalues sharing the same class. The centroids of grayvalue regions sharing the same classification are then tracked with a simple correlation algorithm to establish disparity estimates.

Sutton et al. [1983] propose a correlation method that allows linear deformations of small image regions. A bilinear reconstruction of the intensity surface is computed for local image regions Ω_i . The shift of such an intensity surface under linear deformation is expressed as

$$\mathbf{x}'_{\Omega_i} = \mathbf{x}_{\Omega_i} + \mathbf{d}_{\Omega_i} + \nabla \mathbf{d}_{\Omega_i} \quad (2.30)$$

where \mathbf{x}'_{Ω_i} is the position of the deformed neighborhood Ω_i , $\nabla \mathbf{d}_{\Omega_i}$ are the deformation parameters and \mathbf{d} is the shift of Ω_i in time. A correlation coefficient

$$C(\mathbf{d}_{\Omega_i}, \nabla \mathbf{d}_{\Omega_i}) = \int_D (\Omega_i - \Omega'_i)^2 d\mathbf{x}, \quad (2.31)$$

which describes the squared differences of neighborhoods Ω_i and Ω'_i , is minimized by a search in the motion domain for values of \mathbf{d}_{Ω_i} and $\nabla \mathbf{d}_{\Omega_i}$. The estimates for these six parameters must be obtained iteratively, as no closed-form solution for C is presented.

A region matching method that allows affine deformations of intensity is presented by Kalivas and Sawchuk [1991]. An objective function that is defined in terms of a displacement field undergoing an affine transformation is minimized over the entire image.

In order to avoid the computational expense of iterative minimizations of functionals, Little et al. [1988] suggest that the use of partially overlapping regions for matching is sufficient to approximate an isotropic smoothness term imposed on disparity estimates. Their ap-

proximation of the functional

$$\int_D (\phi(I(\mathbf{x}, t), I(\mathbf{x} + \delta t \mathbf{v}, t + \delta t)) + \lambda(\nabla \mathbf{v} \nabla \mathbf{v}^T)) d\mathbf{x}, \quad (2.32)$$

where ϕ is a correlation operator, is shown to be correct as the extent of the matching region becomes larger.

2.3.2 Hierarchical Approaches

In the presence of large disparities, non-hierarchical correlation algorithms become sensitive to false matches, due to the increase in search spaces required to handle the faster motion. In addition, the correlation of image areas is, in general, computationally intensive. In order to reduce the amount of computations and the potential for mismatches, one may use coarse estimates of motion to direct the matching process. Ogata and Sato's algorithm [1992] provides the correlation computation with coarse estimates of motion obtained from velocity-tuned Gabor filters. These estimates can then be used to restrict the sizes of search areas and thereby reduce the number of computations usually necessary to obtain disparities.

The size of correlation windows is an important parameter for region matching. For instance, within a correlation window, there must be enough variation in the signal to reliably determine disparity. However, the variation of disparity within the same window must remain negligible as local matches operate under the hypothesis of a constant velocity model. The optimal window size then depends on the structure of the underlying signal. Okutomi and Kanade [1990] propose a statistical model of disparity within correlation windows that assumes that disparity values are constant but exhibit increasing uncertainty as they are farther from the central point of the window. This model establishes a relation between the window size and the uncertainty of disparity. This relation allows one to minimize the uncertainty of the

measurements by adjusting the size of the correlation window.

Hierarchical matching techniques can improve the accuracy of the disparities by operating on several frequency channels extracted from the images to be processed. Low-frequency channels are used to estimate large disparities that can be refined by adding higher-frequency channels into the matching process. Anandan's method [1989] is based on a Laplacian pyramid and a coarse-to-fine SSD-based matching strategy. The Laplacian pyramid allows for the estimation of large interframe disparities and helps to enhance image structure, such as edges, that is thought to be important for matching (see Figures 4 and 6). The SSD (sum of squared difference) measure is defined as

$$S(\mathbf{x}, \mathbf{d}) = \sum_{j=-n}^n \sum_{i=-n}^n W(i, j) \times (I(\mathbf{x} + (i, j), t) - I(\mathbf{x} + (i, j), t + 1))^2 \quad (2.33)$$

where $W(i, j)$ denotes a weighting function and \mathbf{d} is restricted to the square neighborhood of size $(2n + 1)^2$ centered at \mathbf{x} . At the coarsest level, the correct displacements are assumed to be one spatial unit per frame or less. SSD minima are first located to integer accuracy within small image regions. Subpixel displacements are then computed by finding the minimum of a quadratic approximation to the SSD surface about the integer location that best minimizes $S(\mathbf{x}, \mathbf{d})$. Confidence measures are derived from the principal curvatures of the SSD surface and used as weights in the functional

$$\int_D \text{tr}((\nabla \mathbf{d})^T (\nabla \mathbf{d})) + c_{\max} (\mathbf{d} \cdot \hat{e}_{\max} - \mathbf{d}_0 \cdot \hat{e}_{\max})^2 + c_{\min} (\mathbf{d} \cdot \hat{e}_{\min} - \mathbf{d}_0 \cdot \hat{e}_{\min})^2 d\mathbf{x} \quad (2.34)$$

which is to be minimized over the entire image velocity domain D . \hat{e}_{\max} and \hat{e}_{\min}

Figure 6. Hierarchical image decomposition: the original images are decomposed in a hierarchical set of frequency channels prior to optic flow estimation.

are the normalized principal directions of maximum and minimum curvature. \mathbf{d}_0 denotes the displacements obtained by the minimization of $S(\mathbf{x}, \mathbf{d})$ in the Laplacian pyramid (usually, three levels are used). At the coarsest level, where the largest motion is assumed to be less than one spatial unit per frame, SSD minima are located to subpixel accuracy by finding the minimum of the SSD correlation surface and smoothed using iterative equations based on (2.34). Then, using an overlapped projection scheme, these displacements are projected to the next level in the pyramid. Matching and smoothing are performed in this manner at each level in the pyramid from the coarsest level down to the finest level, the original

image, yielding the final optical flow field.

Singh's approach [1992] is similar to Anandan's method [1989] as it also uses SSD minimizations and a two-stage computation. The first stage consists of the computation of SSD values with three adjacent high-pass filtered images I_{-1} , I_0 and I_1 . The three-frame SSD surface is computed as

$$S(\mathbf{x}, \mathbf{d}) = S_{0,1}(\mathbf{x}, \mathbf{d}) + S_{0,-1}(\mathbf{x}, -\mathbf{d}). \quad (2.35)$$

The surface S is then converted into a probability distribution, defined as

$$R_c(\mathbf{d}) = e^{-kS(\mathbf{x}, \mathbf{d})}, \quad (2.36)$$

where

$$k = \frac{\ln(0.95)}{\min(S(\mathbf{x}, \mathbf{d}))}.$$

Subpixel velocity estimates \mathbf{d}_c are obtained by computing the weighted average using the $R_c(\mathbf{d})$ values for a given image area. Covariance matrices S_c associated with disparities \mathbf{d}_c are also computed.

The second step of Singh's algorithm propagates velocity using a neighborhood smoothness constraint. Again, a weighted average approach is used in computing \mathbf{d}_a , an average of \mathbf{d}_c over small image regions. \mathbf{d}_c and \mathbf{d}_a are then used to create a covariance matrix S_n . The correct disparity field minimizes the functional

$$\int_D (\mathbf{d} - \mathbf{d}_a) S_n^{-1} (\mathbf{d} - \mathbf{d}_a)^T + (\mathbf{d} - \mathbf{d}_c) S_c^{-1} (\mathbf{d} - \mathbf{d}_c)^T d\mathbf{x}, \quad (2.37)$$

which expresses the requirement of a smoothly varying disparity field across D . The eigenvalues λ_1 and λ_2 of matrix $[S_n + S_c]^{-1}$ act as confidence measures for the estimates. Singh recommends the use of a Laplacian pyramid with a coarse-to-fine strategy as in Anandan [1989] to estimate larger velocities. In addition, Singh's framework was extended with a Kalman filter approach in order to record motion estimates along with their confidence measures and to integrate new measurements with existing estimates [Singh 1991].

2.4 Multiple Motion Methods

Many phenomena can cause multiple image motions. Among them, occlusion and transparency are important in terms of their occurrence and significance in realistic imagery. In addition, their information content is useful in later stages of processing, such as motion segmentation and 3D surface reconstruction. Occlusion boundaries are described by the partial occlusion of a surface by another, whereas transparency is defined as occlusion of a surface by translucent material. In realistic imagery, one finds occlusion to be

the most frequent cause of discontinuous motion.²⁹

Among the limitations inherent to gradient-based methods, the requirement of differentiable intensity structures throughout the image domain is perhaps the most restrictive. At motion discontinuities where most of the information resides, the use of Equation (1.3) becomes problematic, because the intensity derivatives theoretically do not exist. In addition, typical correlation-based techniques are sensitive to occlusion as image structures near occlusion boundaries may appear or disappear in time, possibly leading to mismatches. Furthermore, local optical flow constraints such as (1.3) and local correlation methods are often coupled with global requirements that impose a spatial continuity on optical flow. It is obvious that such isotropic requirements cannot be satisfied in general, as imagery often contains motion discontinuities.

2.4.1 Line Processes

Other functionals that attempt to estimate discontinuous motion have been developed. One strategy to handle occlusion involves using binary line processes that explicitly model intensity discontinuities [Geman and Geman 1984]. Koch et al. [1989] relax the imposition of a smoothness constraint at those pixels having a large spatial gradient. This prevents smoothing over discontinuities and assumes that motion discontinuities occur in the same location as intensity discontinuities [Poggio et al. 1988]. Black [1992] also shows how line processes could be used in a robust (Kalman filter-like) framework.

The nonbinary inhibition of smoothness across intensity contours, was proposed by Nagel [1983a, 1983b, 1987,

²⁹ Prazdny [1985] was one of the first to explicitly allow for disparity discontinuities locally in two stereo images.

1986]. This approach is based on the minimization of the functional

$$\int_D (\nabla I \cdot \mathbf{v} + I_t)^2 + \lambda^2 \text{tr}((\nabla \mathbf{v})^T W (\nabla \mathbf{v})) d\mathbf{x} \quad (2.38)$$

where

$$W = \frac{1}{\|\nabla I\|_2^2 + 2\delta} \begin{pmatrix} I_y^2 + \delta & -I_x I_y \\ -I_x I_y & I_x^2 + \delta \end{pmatrix},$$

in which the quantity $(u_x I_y - u_y I_x)^2 + (v_x I_y - v_y I_x)^2$, representing the spatial variation of \mathbf{v} in the direction perpendicular to the image gradient, is minimized across intensity contours. This functional is known as the *oriented smoothness* constraint. The minimization procedure can be implemented using finite differences [Barron et al. 1994] or finite elements [Kirchner and Niemann 1992; Schnorr 1992]. This oriented smoothness approach has been recently extended into the temporal domain [Nagel 1990]. A similar method using an intensity-weighted smoothing procedure is presented by Aisbett [1989]. This approach is characterized by the inhibition of an isotropic smoothness constraint for image regions containing significant intensity variations. Contrary to Nagel's method [1987], the inhibition of the smoothness constraint is not directional. In addition, the image intensities are assumed differentiable and the domain of application of the algorithm is explicitly restricted to images that satisfy this requirement.

Closed curves may also be used to separate image regions exhibiting different velocities. Schnörr [1992] proposes a method that consists of defining such a curve, delimiting an arbitrary area around the region where the existence of an independently moving object is assumed, thus creating two domains Ω_i and Ω_o . Given two velocity fields \mathbf{v}_i and \mathbf{v}_o , the closed curve defining the two domains is iteratively refined by minimiz-

ing the functional

$$\int_{\Omega_i} f(\hat{\mathbf{v}}_i, \mathbf{v}_i) d\mathbf{x} + \int_{\Omega_o} g(\hat{\mathbf{v}}_o, \mathbf{v}_i) d\mathbf{x} \quad (2.39)$$

where $f = (\hat{\mathbf{v}}_i - \mathbf{v}_i)^2$, $g = (\hat{\mathbf{v}}_o - \mathbf{v}_i)^2$ and $\hat{\mathbf{v}}_i$ and $\hat{\mathbf{v}}_o$ are measured velocities within Ω_i and Ω_o , respectively. However, assuming a priori knowledge about the position of the independently moving object limits the generality of this method.

2.4.2 Mixed Velocity Distributions

Another strategy for estimating discontinuous optical flow is to make explicit a model for mixed velocity distributions (usually two) at each image point. A method of estimating discontinuous motion on a local basis, presented by Schunck [1989], uses the optical flow constraint equation (1.3) to compute several constraint lines in velocity space for small spatial neighborhoods. Clusters of intersections of these lines with the constraint line of the central point of the neighborhood are analyzed to determine the smallest cluster containing at least half the intersection points. The middle point of this cluster thus defines the motion estimate \mathbf{v} . If two motion patterns are present within the neighborhood, then \mathbf{v} is considered as the dominant one. Hence, velocity can be correctly estimated across motion boundaries (see Figure 7). However, neighborhood sizes must include significant constraint line variations, as finding intersections of constraint lines may become ill-conditioned otherwise (this is simply another manifestation of the aperture problem). Jepson and Black's *mixture models* [1993] also follow this approach, but use a robust estimation framework.

When multiple motions arise within a single image region, a least squares solution to the optical flow constraint line clustering problem leads to an average estimate of these multiple motions. Noting that difficulty, Black [1991, 1992, 1990] reformulates the problem of estimating optical flow by using *robust* estimators. This framework consists of the

Figure 7. The constraint line from the central point of the image region being considered intersects with the constraint lines of neighboring image points.

minimization of a functional that expresses the various assumptions made about image motion:

$$E(\mathbf{v}, \bar{\mathbf{v}}) = \lambda_D E_D(\mathbf{v}) + \lambda_S E_S(\mathbf{v}) + \lambda_T E_T(\mathbf{v}, \bar{\mathbf{v}}), \quad (2.40)$$

where $E_D(\mathbf{v})$ is the optical flow constraint equation, $E_S(\mathbf{v})$ is a spatial coherence constraint (a spatial smoothness term) and $E_T(\mathbf{v}, \bar{\mathbf{v}})$ is a temporal coherence constraint:

$$E_T(\mathbf{v}, \bar{\mathbf{v}}) = \rho_T(\mathbf{v} - \bar{\mathbf{v}}, \sigma_t) \quad (2.41)$$

$$E_D(\mathbf{v}) = \rho_D(\nabla I \cdot \mathbf{v} + I_t, \sigma_d) \quad (2.42)$$

$$E_S(\mathbf{v}) = \sum_{n \in \Omega} \rho_S(\mathbf{v} - \mathbf{v}_n, \sigma_s). \quad (2.43)$$

$\bar{\mathbf{v}}$ is a prediction about \mathbf{v} at time $t + 1$. ρ_D , ρ_S , and ρ_T are *robust*, Lorentzian M -estimators. Their use is motivated by the fact that the distribution of multiple motions within a single image region is not Gaussian and to account for events unmodeled by the brightness constancy assumption. The robustness of these statistical estimators is characterized by their relative insensitivity to deviations from the assumed statistical model in the set of measurements, allowing the estimation of discontinuous optical flows. In Figure 8 the influence function of the Lorentzian probability distribution tends to zero rapidly for deviations from the

mean. These are considered outliers [Black 1992].

Multiple patterns of motion within a single image region also arise from partial transparency of occluding surfaces. Bergen et al. [1992] present an algorithm for estimating up to two different motions within a single intensity neighborhood. The algorithm uses the following steps: let \mathbf{v}_1 and \mathbf{v}_2 be two distinct velocities within an arbitrary image region. An iterative process is applied for estimating \mathbf{v}_1 and warping the corresponding image region in the next two frames to compute two difference images, D_1 and D_2 , used in turn to estimate \mathbf{v}_2 . If \mathbf{v}_1 is a reasonable estimate of one velocity pattern then the residual intensity structure in D_1 and D_2 reflects the velocity \mathbf{v}_2 . The algorithm is iterated until the estimates \mathbf{v}_1 and \mathbf{v}_2 stabilize. It is generally sufficient to assume $\mathbf{v}_1 = \mathbf{v}_2 = \mathbf{0}$ initially, if no a priori knowledge is available. A least squares method is employed for solving \mathbf{v}_1 and \mathbf{v}_2 , using (1.3).

Other approaches for the measurement of multiple motions exist: the distribution of motion patterns may be regarded as a superposition of data distributions. Shizawa and Mase [1991] apply a superposition principle to multiple motions and show that existing algorithms for optical flow, 3D motion and structure, etc., can be generalized to handle many motion

Figure 8. (a) A least squares fit through a cloud of points. (b) A robust fit through the same cloud of points.

distributions. Similarly, multiple motions can be thought of as a set of layers, each describing a particular motion, over a particular domain. Techniques to separate these layers have been proposed by many authors: Darrell and Pentland [1991] explicitly take the support of homogeneous regions into account by using a multi-layer, cooperative, robust estimation framework. Jepson and Black [1993] use an expectation-maximization (EM) algorithm to group a wide variety of component velocities into a fixed number of layers. Irani et al. [1994] determine a dominant motion in an image using a least squares approach and then group and segment the outlying motions. Their approach assumes that there is only one dominant motion and many outlying motions, each of which is assumed to correspond to independently moving objects. Adiv [1985] uses a Hough transform on a precomputed optical flow field to group regions having velocities consistent with roughly planar surfaces. This grouping is based on finding neighboring velocities sharing the same affine transformations. Negahdaripour and Lee [1992] present a segmentation process based on a hierarchical clustering method that does not assume a precomputed optical flow field. They fit an affine model to small regions of the image and then repeatedly merge neighboring regions based on similarity of their affine parameters. Then, given

two sufficiently large planar regions, a motion and structure calculation can be performed. Wang and Adelson [1994] use a clustering algorithm to group velocities into layers, each consistent with an affine motion. Bober and Kittler [1994] use a block-based Hough transform in a robust estimation framework (redescending kernels) to obtain robust velocity estimates, including multiple motions, by clustering coherent motions at the same time the motion estimation is performed. Two confidence measures based on support functions are also proposed. In addition, hierarchical frameworks are known to separate motion components with respect to spatiotemporal frequencies. Burt et al. [1991] suggest that multiple motions could be handled separately using different spatiotemporal frequency channels.

2.4.3 Parametric Models

Parametric models generally describe image motion with bivariate polynomials of varying order in the image coordinates and provide strong constraints on motion, which usually results in the accurate inference of optical flow [Black and Jepson 1994]. These models possess desirable qualities: the motion of large image regions may be described with a single set of parameters, due to the increased flexibility of representation. In addition, parametric models are ade-

quate for the description of discontinuous optical flow as each segmented region may be described with a particular set of motion parameters.

Bergen et al. [1992] consider the computation of optical flow from the viewpoint of image registration: given an image sequence, the parameters that best align an image with the next in the sequence are to be computed. This framework unifies many of the approaches already surveyed. In all cases, a function is to be minimized with respect to different parameters modeling velocity. Their algorithm has four basic components: pyramid construction, motion estimation, image warping, and coarse-to-fine refinement. A Laplacian pyramid is used to hierarchically represent the image data [Burt and Adelson 1983], and motion estimation is performed by SSD minimization with respect to a particular model of motion. Image warping uses the current parameter values to compute an optical flow field at time t and then reconstructs another image at time t from the image at time $t - 1$. Image reconstruction is performed using bilinear interpolation. The warped image is then compared with the original image and an error measure, based on image difference, is minimized with the Gauss-Newton method. The last component is a propagation of motion estimates from one level in the pyramid to the next lower level where they are used as initial guesses for the iterative refinement.

Using Bergen et al.'s [1992] classification, the optical flow methods previously presented can be thought of as parametric, quasiparametric, or nonparametric. Parametric models fully describe the individual motion with a bivariate equation. For example, affine models approximate image velocity as:

$$\begin{aligned} u(x, y) &= a_1(x, y) + a_2x + a_3y \\ v(x, y) &= a_4(x, y) + a_5x + a_6y, \end{aligned} \quad (2.44)$$

which is reasonably valid when surfaces are far from the observer or the image region under analysis is small. This models optical flow as a superposition of uni-

form motion and rotation, dilation, and shear. This is the model used by Fleet and Jepson [1990, 1992] to integrate component velocities in local neighborhoods. Adiv [1985] also uses this model to segment and fit velocity measurements to local planar patches in the first stage of his algorithm. Spetsakis [1994] uses an affine flow model and a hierarchy of Gabor filters. A second model assumes planarity of local surfaces:

$$\begin{aligned} u(x, y) &= a_1(x, y) + a_2x + a_3y \\ &\quad + a_7x^2 + a_8xy \\ v(x, y) &= a_4(x, y) + a_5x + a_6y \\ &\quad + a_7xy + a_8y^2, \end{aligned} \quad (2.45)$$

which is the *velocity functional method* of Waxman and Wohn [1985] which they extended to include second-order curved surfaces. In both (2.44) and (2.45) the a_i 's are neighborhood center velocities or first- and second-order velocity derivatives. These parameters completely describe a planar surface velocity field. Any constant velocity model, such as Lucas and Kanade's [1981], is also an example of a parametric model for general motion [Bergen et al. 1992]. Usually, the order of a parametric model describes its applicability for large image regions.

Nonparametric models are those typically used in global optical flow recovery. Horn and Schunck's global smoothness [1981] or Nagel's oriented smoothness constraint [1987] are examples of nonparametric models. Quasiparametric models use a combination of parametric and nonparametric models. Bergen et al. place rigid motion models in this class. Rigid motion arises from rigidly moving scene objects under perspective projection. Direct motion and structure methods are examples of this model: Hanna [1991, 1993] shows that the rigidity assumption can be used to overcome the aperture problem in most cases. These parametric models are presented in a unified hierarchical framework [Bergen et al. 1992]. The hierarchy yields in-

creased computational efficiency and also allows for increased accuracy and robustness via coarse-to-fine refinements and image warping.

Black and Jepson [1994] determine coarse optical flow via a correlation method [Black and Anandan 1993] and fit parametric models to segmented regions of the image by hypothesizing local planarity and using coarse velocities to perform segmentation. Standard area-based regression techniques further refine these motion estimates. Deviations from planarity are modeled by allowing local deformations in the motion estimates. Hence, their approach does not try to fit a single parametric model to the whole image, but many parametric models to individual segmented regions. Also, Haddadi and Kuo [1992] propose a parametric smoothness model that decomposes optical flow into irrotational and solenoidal fields and imposes a smoothness constraint on each field separately. Parameters are iteratively improved and smoothing across motion boundaries is avoided.

2.5 Temporal Refinement Methods

Most of the preceding methods for computing optical flow do not incorporate motion estimates from previous calculations within an image sequence being acquired: given two or more images, optical flow is computed only for one of the images. Recently, there has been some interest in incremental computation of optical flow.³⁰ The advantages include instantaneous access to optimal velocity estimates, accuracy improvement as the integration of optical flow over time is performed, computational efficiency gained by updating the estimates with the current frame, and the ability to adapt to discontinuous optical flow as the observer or scene objects abruptly vary their motions.

Black's [1992] algorithm may also be viewed as an incremental model because it minimizes an objective function that incorporates conversion of image intensity and spatiotemporal coherence in a robust estimation framework. Temporal continuity allows prediction of the next image velocity, assuming uniform acceleration. Warping with bilinear interpolation is used to estimate the acceleration. Black and Anandan [1991] use a Markov random field (MRF) method in a reformulation of Black's approach. The MRF algorithm is parallel, local, and detects occlusion boundaries in an incremental fashion but, as formulated, can only handle integer motions. Singh [1991] uses a Kalman filter to integrate velocity estimates computed by a hierarchical correlation method [Singh 1990]. The Kalman filter reduces the uncertainty of the estimates over time. This framework also detects occlusion boundaries. Fleet and Langley [1995a] use low-pass recursive filters to produce and update gradient-based velocity estimates from a sequence of images. Chin et al. [1994] present an extension of Horn and Schunck's [1981] dense optical flow algorithm that uses a temporal coherence constraint to produce near optimal, recursive flow estimates from multiple frames.

3. DISCUSSION

Although many methods and strategies have appeared, the estimation of image motion remains a challenging task: to date, except in limited circumstances, no technique is able to generate sufficiently accurate and dense optical flow fields to allow the general recovery of motion and scene parameters in a realistic environment. In fact, motion and structure algorithms need very accurate optical flow to carry useful 3D motion and structure computations [Barron et al. 1990]. Also needed are accurate means of determining the reliability of computed image velocities. Such reliability measures have been proposed: covariance matrix eigenvalues [Simoncelli et al. 1991; Singh 1992], Gaussian curvature [Uras et al.

³⁰ See Black [1992], Black and Anandan [1993], Singh [1991], Fleet and Langley [1995b], Chin et al. [1994].

1988], principal curvature [Anandan 1989; Heeger 1988], spatial gradient [Barron et al. 1994], eigenvalues of a least squares matrix [Simoncelli et al. 1991], and support function values [Bober and Kittler 1994]. These confidence measures allow for thresholding, yielding more accurate but sparser optical flow fields. They may also be integrated in subsequent processing, such as weights in a least squares motion and structure calculation.

Of importance in an accurate estimation of image motion in the surveyed methods is the requirement for appropriate spatiotemporal sampling rates, in order to compute accurate spatiotemporal derivatives for differential-based methods, to reduce the search areas for matching-based methods, or to limit the amount of aliasing when estimating optical flow with frequency-based filtering methods. Too often, the assumption that imagery is free of aliasing effects is made. Conventional cameras usually produce imagery with severe temporal aliasing, especially for significant image motions. Reducing aliasing effects may be accomplished by increasing temporal sampling rates, image prefiltering, or by using hierarchical processing. Of course, increased temporal sampling rates lead to more accurate optical flow computations. However, for a number of reasons, including small temporal support (only a few images) or fast image motion, such appropriately sampled imagery is not always available. In such cases, accurate temporal derivatives may be difficult to obtain and hierarchical matching-based methods seem to be a natural choice. It has also been observed that some prefiltering of the image sequence prior to the extraction of basic image motion measurements, such as intensity derivatives or correlation surfaces, significantly increases the accuracy of results [Barron et al. 1994]. For instance, a spatiotemporal Gaussian smoothing of the image sequence results in more accurate derivatives for the methods of Lucas and Kanade [1984, 1981] and Horn and Schunck [1981]. Anandan's [1989] and

Singh's [1992] computational schemes also use prefiltering of the images by computing hierarchical Laplacian images. It is believed that this high-pass filtering emphasizes image structures that are desirable for correlation.

Often, very restrictive assumptions about image motion are posed. For example, one of these assumptions requires neighboring velocities arising from the relative motion of a single surface to be similar [Horn and Schunck 1981]. This requirement is usually imposed by applying isotropic smoothness constraints onto velocity estimates. However, only a few simple cases of realistic imagery exhibit continuous motion fields: realistic images, such as outdoor scenes, possess complex structures for which global single surface assumptions are inadequate. Attempts at estimating discontinuous image motion are proposed by Cornelius and Kanade [1983] and Nagel [1983a, 1987, 1990] in the form of an inhibition of the smoothness requirement across intensity discontinuities. However, it is obvious that intensity discontinuities may not necessarily represent motion discontinuities [Thompson et al. 1985]. The problem posed by occluding surfaces needs further investigation. Occlusion is an important source of visual information: optical flow at occlusion boundaries can be used to determine the direction of translation (the focus of expansion) [Longuet-Higgins and Prazdny 1980] and segment the scene into independently moving objects [Thompson and Pong 1990], yet optical flow estimation at occlusions is problematic. Adequate approaches to handling occlusion include line approaches that explicitly model intensity discontinuities and prevent smoothing over them, layered or superposed parametric models, and mixed velocity distribution models that assume the presence of usually two velocities and discriminate them according to some criteria. In addition, occlusion has been recently analytically described in Fourier space [Beauchemin and Barron 1995; Fleet and Langley 1995a].

Alternatively, optical flow may be esti-

mated with local constraints only.³¹ In these schemes, no smoothness requirements are imposed and motion discontinuities may be preserved. Of course, the accuracy at motion boundaries or at regions of transparency highly depends on the model of motion being used. For instance, single motion models are inadequate for handling occlusion and transparency properly. Nonetheless, the use of local constraints or parametric models may be more appropriate in general [Barron et al. 1994], as no arbitrary smoothness requirement is imposed on the structure of optical flow.

Lighting effects also constitute a problem in many image sequences. Constant scene illumination and Lambertian surface reflectance are either implicitly or explicitly assumed for most current optical flow methods that use the brightness constancy assumption. Although the effects of highlights, shadows, and illumination conditions on the estimation of optical flow have only been studied to a limited degree, it is possible to partially compensate for these effects and estimate image motion as a geometric quantity if the characteristics of the light sources are known. Towards this, the use of multiple light sources [Woodham 1990] and sets of multispectral constraints on image motion [Markandey and Flinchbaugh 1990] have been used. Shading effects have also been modeled [Mukawa 1993].

Aside from lighting conditions, some surface reflectance phenomena also pose difficulties. For example, transparent surfaces usually lead to multiple motions whereas highlights may create false motions. Perhaps due to their difficulty and infrequency of occurrence, transparent motions have been mainly ignored and attempts at estimating multiple motions have just begun to appear [Bergen et al.

1992; Jepson and Black 1993]. Methods using orientation- and velocity-sensitive filters may contribute to the solving of this particular problem, as they provide multiple measurements for each location [Fleet and Jepson 1990]. Alternatively, superposition principles and layered motions [Darrell and Pentland 1991; Shizawa and Mase 1991; Wang and Adelson 1994] are promising frameworks. However, segmenting multiple motion distributions remains difficult if no a priori assumption is made on the number of distributions present within a support region.

Lastly, we would like to emphasize that much of the image motion literature presents flow field examples for a few image sequences, which can only be judged qualitatively. Although the *theory* of optical flow computation is being addressed, the *practice* of optical flow is often neglected: far too little of the published work provides quantitative error analysis. Usually, only a qualitative comparison is possible. Even then, it is often difficult to assess which techniques are quantitatively better as authors typically use their favorite image sequences, which are not usually available to the community and for which the correct image motion is unknown. A widely available set of images for comparative testing is needed. These images should have known optical flow fields and allow a quantitative error analysis. This is especially the case for the newer work, as with the layered approaches to optical flow, where little or no quantitative analysis exists.

There are various means of performing quantitative error analysis when correct optical flow information is available: error can be expressed as absolute error, relative error, angle error [Fleet and Jepson 1990], RMS, or SNR ratios, allowing one to compare optical flows for the same image sequence. Furthermore, quantitative analysis is possible without motion information: RMS image reconstruction error has been used to measure error for real image sequences when the

correct motion information is unavailable.³²
